Getting Started

Welcome to Asynchronous Programming in Rust! If you're looking to start writing asynchronous Rust code, you've come to the right place. Whether you're building a web server, a database, or an operating system, this book will show you how to use Rust's asynchronous programming tools to get the most out of your hardware.

What This Book Covers

This book aims to be a comprehensive, up-to-date guide to using Rust's async language features and libraries, appropriate for beginners and old hands alike.

- The early chapters provide an introduction to async programming in general, and to Rust's particular take on it.
- The middle chapters discuss key utilities and control-flow tools you can use when writing async code, and describe best-practices for structuring libraries and applications to maximize performance and reusability.
- The last section of the book covers the broader async ecosystem, and provides a number of examples of how to accomplish common tasks.

With that out of the way, let's explore the exciting world of Asynchronous Programming in Rust!

Why Async?

We all love how Rust allows us to write fast, safe software. But why write asynchronous code?

Asynchronous code allows us to run multiple tasks concurrently on the same OS thread. In a typical threaded application, if you wanted to download two different webpages at the same time, you would spread the work across two different threads, like this:

```
fn get_two_sites() {
    // Spawn two threads to do work.
    let thread_one = thread::spawn(|| download("https://www.foo.com"));
    let thread_two = thread::spawn(|| download("https://www.bar.com"));

    // Wait for both threads to complete.
    thread_one.join().expect("thread one panicked");
    thread_two.join().expect("thread two panicked");
}
```

This works fine for many applications-- after all, threads were designed to do just this: run multiple different tasks at once. However, they also come with some limitations. There's a lot of overhead involved in the process of switching between different threads and sharing data between threads. Even a thread which just sits and does nothing uses up valuable system resources. These are the costs that asynchronous code is designed to eliminate. We can rewrite the function above using Rust's `async` / `.await` notation, which will allow us to run multiple tasks at once without creating multiple threads:

```
async fn get_two_sites_async() {
    // Create two different "futures" which, when run to completion,
    // will asynchronously download the webpages.
    let future_one = download_async("https://www.foo.com");
    let future_two = download_async("https://www.bar.com");

    // Run both futures to completion at the same time.
    join!(future_one, future_two);
}
```

Overall, asynchronous applications have the potential to be much faster and use fewer resources than a corresponding threaded implementation. However, there is a cost. Threads are natively supported by the operating system, and using them doesn't require any special programming model-- any function can create a thread, and calling a function that uses threads is usually just as easy as calling any normal function. However, asynchronous functions require special support from the language or libraries. In Rust, `async fn` creates an asynchronous function which returns a `Future`. To execute the body of the function, the returned `Future` must be run to completion.

It's important to remember that traditional threaded applications can be quite effective, and that Rust's small memory footprint and predictability mean that you can get far without ever using `async`. The increased complexity of the asynchronous programming model isn't always worth it, and it's important to consider whether your application would be better served by using a simpler threaded model.

The State of Asynchronous Rust

The asynchronous Rust ecosystem has undergone a lot of evolution over time, so it can be hard to know what tools to use, what libraries to invest in, or what documentation to read. However, the `Future` trait inside the standard library and the `async` / `await` language feature has recently been stabilized. The ecosystem as a whole is therefore in the midst of migrating to the newly-stabilized API, after which point churn will be significantly reduced.

At the moment, however, the ecosystem is still undergoing rapid development and the asynchronous Rust experience is unpolished. Most libraries still use the 0.1 definitions of the `futures` crate, meaning that to interoperate developers frequently need to reach for the `compat` functionality from the 0.3 `futures` crate. The `async` / `await` language feature is still new. Important extensions like `async fn` syntax in trait methods are still unimplemented, and the current compiler error messages can be difficult to parse.

That said, Rust is well on its way to having some of the most performant and ergonomic support for asynchronous programming around, and if you're not afraid of doing some spelunking, enjoy your dive into the world of asynchronous programming in Rust!

`async`/`.await` Primer

`async`/`.await` is Rust's built-in tool for writing asynchronous functions that look like synchronous code. `async` transforms a block of code into a state machine that implements a trait called `Future`. Whereas calling a blocking function in a synchronous method would block the whole thread, blocked `Future`s will yield control of the thread, allowing other `Future`s to run.

Let's add some dependencies to the `Cargo.toml` file:

```
[dependencies]
futures = "0.3"
```

To create an asynchronous function, you can use the `async fn` syntax:

```
async fn do_something() { /* ... */ }
```

The value returned by `async fn` is a `Future`. For anything to happen, the `Future` needs to be run on an executor.

```
// `block_on` blocks the current thread until the provided future has run to
// completion. Other executors provide more complex behavior, like scheduling
// multiple futures onto the same thread.
use futures::executor::block_on;

async fn hello_world() {
    println!("hello, world!");
}

fn main() {
    let future = hello_world(); // Nothing is printed
    block_on(future); // `future` is run and "hello, world!" is printed
}
```

Inside an `async fn`, you can use `.await` to wait for the completion of another type that implements the `Future` trait, such as the output of another `async fn`. Unlike `block_on`, `.await` doesn't block the current thread, but instead asynchronously waits for the future to complete, allowing other tasks to run if the future is currently unable to make progress.

For example, imagine that we have three `async fn`: `learn_song`, `sing_song`, and `dance`:

```
async fn learn_song() -> Song { /* ... */ }
async fn sing_song(song: Song) { /* ... */ }
async fn dance() { /* ... */ }
```

One way to do learn, sing, and dance would be to block on each of these individually:

```
fn main() {
    let song = block_on(learn_song());
    block_on(sing_song(song));
    block_on(dance());
}
```

However, we're not giving the best performance possible this way-- we're only ever doing one thing at once! Clearly we have to learn the song before we can sing it, but it's possible to dance at the same time as learning and singing the song. To do this, we can create two separate `async fn` which can be run concurrently:

```
async fn learn_and_sing() {
    // Wait until the song has been learned before singing it.
    // We use `.await` here rather than `block_on` to prevent blocking the
    // thread, which makes it possible to `dance` at the same time.
    let song = learn_song().await;
    sing_song(song).await;
}

async fn async_main() {
    let f1 = learn_and_sing();
    let f2 = dance();

    // `join!` is like `.await` but can wait for multiple futures concurrently.
    // If we're temporarily blocked in the `learn_and_sing` future, the `dance`
    // future will take over the current thread. If `dance` becomes blocked,
    // `learn_and_sing` can take back over. If both futures are blocked, then
    // `async_main` is blocked and will yield to the executor.
    futures::join!(f1, f2);
}

fn main() {
    block_on(async_main());
}
```

In this example, learning the song must happen before singing the song, but both learning and singing can happen at the same time as dancing. If we used `block_on(learn_song())` rather than `learn_song().await` in `learn_and_sing`, the thread wouldn't be able to do anything else while `learn_song` was running. This would make it impossible to dance at the same time. By `.await`-ing the `learn_song` future, we allow other tasks to take over the current thread if `learn_song` is blocked. This makes it possible to run multiple futures to completion concurrently on the same thread.

Now that you've learned the basics of `async`/`await`, let's try out an example.

Applied: Simple HTTP Server

Let's use `async` / `.await` to build an echo server!

To start, run `rustup update stable` to make sure you've got stable Rust 1.39 or newer. Once you've done that, run `cargo new async-await-echo` to create a new project, and open up the resulting `async-await-echo` folder.

Let's add some dependencies to the `Cargo.toml` file:

```
[dependencies]
# Hyper is an asynchronous HTTP library. We'll use it to power our HTTP
# server and to make HTTP requests.
hyper = "0.13"
# To setup some sort of runtime needed by Hyper, we will use the Tokio runtime.
tokio = { version = "0.2", features = ["full"] }

# (only for testing)
anyhow = "1.0.31"
reqwest = { version = "0.10.4", features = ["blocking"] }
```

Now that we've got our dependencies out of the way, let's start writing some code. We have some imports to add:

```
use {
    hyper::{
        // Following functions are used by Hyper to handle a `Request`
        // and returning a `Response` in an asynchronous manner by using a
Future
        service::{make_service_fn, service_fn},
        // Miscellaneous types from Hyper for working with HTTP.
        Body,
        Client,
        Request,
        Response,
        Server,
        Uri,
    },
    std::net::SocketAddr,
};
```

Once the imports are out of the way, we can start putting together the boilerplate to allow us to serve requests:

```
async fn serve_req(_req: Request<Body>) -> Result<Response<Body>, hyper::Error>
{
    // Always return successfully with a response containing a body with
    // a friendly greeting ;)
    Ok(Response::new(Body::from("hello, world!")))
}

async fn run_server(addr: SocketAddr) {
    println!("Listening on http://{}", addr);

    // Create a server bound on the provided address
    let serve_future = Server::bind(&addr)
        // Serve requests using our `async serve_req` function.
        // `serve` takes a type which implements the `MakeService` trait.
        // `make_service_fn` converts a closure into a type which
        // implements the `MakeService` trait. That closure must return a
        // type that implements the `Service` trait, and `service_fn`
        // converts a request-response function into a type that implements
        // the `Service` trait.
        .serve(make_service_fn(|_| async {
            Ok::<_, hyper::Error>(service_fn(serve_req))
        }));

    // Wait for the server to complete serving or exit with an error.
    // If an error occurred, print it to stderr.
    if let Err(e) = serve_future.await {
        eprintln!("server error: {}", e);
    }
}

#[tokio::main]
async fn main() {
  // Set the address to run our socket on.
  let addr = SocketAddr::from(([127, 0, 0, 1], 3000));

  // Call our `run_server` function, which returns a future.
  // As with every `async fn`, for `run_server` to do anything,
  // the returned future needs to be run using `await`;
  run_server(addr).await;
}
```

If you `cargo run` now, you should see the message "Listening on http://127.0.0.1:3000" printed on your terminal. If you open that URL in your browser of choice, you'll see "hello, world!" appear in your browser. Congratulations! You just wrote your first asynchronous webserver in Rust.

You can also inspect the request itself, which contains information such as the request URI, HTTP version, headers, and other metadata. For example, we can print out the URI of the request like this:

```
println!("Got request at {:?}", _req.uri());
```

You may have noticed that we're not yet doing anything asynchronous when handling the request-- we just respond immediately, so we're not taking advantage of the flexibility that

`async fn` gives us. Rather than just returning a static message, let's try proxying the user's request to another website using Hyper's HTTP client.

We start by parsing out the URL we want to request:

```
        let url_str = "http://www.rust-lang.org/en-US/";
        let url = url_str.parse::<Uri>().expect("failed to parse URL");
```

Then we can create a new `hyper::Client` and use it to make a `GET` request, returning the response to the user:

```
        let res = Client::new().get(url).await?;
        // Return the result of the request directly to the user
        println!("request finished-- returning response");
        Ok(res)
```

`Client::get` returns a `hyper::client::ResponseFuture`, which implements `Future<Output = Result<Response<Body>>>` (or `Future<Item = Response<Body>, Error = Error>` in futures 0.1 terms). When we `.await` that future, an HTTP request is sent out, the current task is suspended, and the task is queued to be continued once a response has become available.

Now, if you `cargo run` and open `http://127.0.0.1:3000/foo` in your browser, you'll see the Rust homepage, and the following terminal output:

```
Listening on http://127.0.0.1:3000
Got request at /foo
making request to http://www.rust-lang.org/en-US/
request finished-- returning response
```

Congratulations! You just proxied an HTTP request.

Under the Hood: Executing Futures and Tasks

In this section, we'll cover the underlying structure of how `Future`s and asynchronous tasks are scheduled. If you're only interested in learning how to write higher-level code that uses existing `Future` types and aren't interested in the details of how `Future` types work, you can skip ahead to the `async`/`await` chapter. However, several of the topics discussed in this chapter are useful for understanding how `async`/`await` code works, understanding the runtime and performance properties of `async`/`await` code, and building new asynchronous primitives. If you decide to skip this section now, you may want to bookmark it to revisit in the future.

Now, with that out of the way, let's talk about the `Future` trait.

The `Future` Trait

The `Future` trait is at the center of asynchronous programming in Rust. A `Future` is an asynchronous computation that can produce a value (although that value may be empty, e.g. `()`). A *simplified* version of the future trait might look something like this:

```
trait SimpleFuture {
    type Output;
    fn poll(&mut self, wake: fn()) -> Poll<Self::Output>;
}

enum Poll<T> {
    Ready(T),
    Pending,
}
```

Futures can be advanced by calling the `poll` function, which will drive the future as far towards completion as possible. If the future completes, it returns `Poll::Ready(result)`. If the future is not able to complete yet, it returns `Poll::Pending` and arranges for the `wake()` function to be called when the `Future` is ready to make more progress. When `wake()` is called, the executor driving the `Future` will call `poll` again so that the `Future` can make more progress.

Without `wake()`, the executor would have no way of knowing when a particular future could make progress, and would have to be constantly polling every future. With `wake()`, the executor knows exactly which futures are ready to be `poll`ed.

For example, consider the case where we want to read from a socket that may or may not have data available already. If there is data, we can read it in and return `Poll::Ready(data)`, but if no data is ready, our future is blocked and can no longer make progress. When no data is available, we must register `wake` to be called when data becomes ready on the socket, which will tell the executor that our future is ready to make progress. A simple `SocketRead` future might look something like this:

```
pub struct SocketRead<'a> {
    socket: &'a Socket,
}

impl SimpleFuture for SocketRead<'_> {
    type Output = Vec<u8>;

    fn poll(&mut self, wake: fn()) -> Poll<Self::Output> {
        if self.socket.has_data_to_read() {
            // The socket has data-- read it into a buffer and return it.
            Poll::Ready(self.socket.read_buf())
        } else {
            // The socket does not yet have data.
            //
            // Arrange for `wake` to be called once data is available.
            // When data becomes available, `wake` will be called, and the
            // user of this `Future` will know to call `poll` again and
            // receive data.
            self.socket.set_readable_callback(wake);
            Poll::Pending
        }
    }
}
```

This model of `Future`s allows for composing together multiple asynchronous operations without needing intermediate allocations. Running multiple futures at once or chaining futures together can be implemented via allocation-free state machines, like this:

```
/// A SimpleFuture that runs two other futures to completion concurrently.
///
/// Concurrency is achieved via the fact that calls to `poll` each future
/// may be interleaved, allowing each future to advance itself at its own pace.
pub struct Join<FutureA, FutureB> {
    // Each field may contain a future that should be run to completion.
    // If the future has already completed, the field is set to `None`.
    // This prevents us from polling a future after it has completed, which
    // would violate the contract of the `Future` trait.
    a: Option<FutureA>,
    b: Option<FutureB>,
}

impl<FutureA, FutureB> SimpleFuture for Join<FutureA, FutureB>
where
    FutureA: SimpleFuture<Output = ()>,
    FutureB: SimpleFuture<Output = ()>,
{
    type Output = ();
    fn poll(&mut self, wake: fn()) -> Poll<Self::Output> {
        // Attempt to complete future `a`.
        if let Some(a) = &mut self.a {
            if let Poll::Ready(()) = a.poll(wake) {
                self.a.take();
            }
        }

        // Attempt to complete future `b`.
        if let Some(b) = &mut self.b {
            if let Poll::Ready(()) = b.poll(wake) {
                self.b.take();
            }
        }

        if self.a.is_none() && self.b.is_none() {
            // Both futures have completed-- we can return successfully
            Poll::Ready(())
        } else {
            // One or both futures returned `Poll::Pending` and still have
            // work to do. They will call `wake()` when progress can be made.
            Poll::Pending
        }
    }
}
```

This shows how multiple futures can be run simultaneously without needing separate allocations, allowing for more efficient asynchronous programs. Similarly, multiple sequential futures can be run one after another, like this:

```
/// A SimpleFuture that runs two futures to completion, one after another.
//
// Note: for the purposes of this simple example, `AndThenFut` assumes both
// the first and second futures are available at creation-time. The real
// `AndThen` combinator allows creating the second future based on the output
// of the first future, like `get_breakfast.and_then(|food| eat(food))`.
pub struct AndThenFut<FutureA, FutureB> {
    first: Option<FutureA>,
    second: FutureB,
}

impl<FutureA, FutureB> SimpleFuture for AndThenFut<FutureA, FutureB>
where
    FutureA: SimpleFuture<Output = ()>,
    FutureB: SimpleFuture<Output = ()>,
{
    type Output = ();
    fn poll(&mut self, wake: fn()) -> Poll<Self::Output> {
        if let Some(first) = &mut self.first {
            match first.poll(wake) {
                // We've completed the first future-- remove it and start on
                // the second!
                Poll::Ready(()) => self.first.take(),
                // We couldn't yet complete the first future.
                Poll::Pending => return Poll::Pending,
            };
        }
        // Now that the first future is done, attempt to complete the second.
        self.second.poll(wake)
    }
}
```

These examples show how the `Future` trait can be used to express asynchronous control flow without requiring multiple allocated objects and deeply nested callbacks. With the basic control-flow out of the way, let's talk about the real `Future` trait and how it is different.

```
trait Future {
    type Output;
    fn poll(
        // Note the change from `&mut self` to `Pin<&mut Self>`:
        self: Pin<&mut Self>,
        // and the change from `wake: fn()` to `cx: &mut Context<'_>`:
        cx: &mut Context<'_>,
    ) -> Poll<Self::Output>;
}
```

The first change you'll notice is that our `self` type is no longer `&mut Self`, but has changed to `Pin<&mut Self>`. We'll talk more about pinning in a later section, but for now know that it allows us to create futures that are immovable. Immovable objects can store pointers between their fields, e.g. `struct MyFut { a: i32, ptr_to_a: *const i32 }`. Pinning is necessary to enable async/await.

Secondly, `wake: fn()` has changed to `&mut Context<'_>`. In `SimpleFuture`, we used a call to a function pointer (`fn()`) to tell the future executor that the future in question should be polled. However, since `fn()` is just a function pointer, it can't store any data about *which* `Future` called `wake`.

In a real-world scenario, a complex application like a web server may have thousands of different connections whose wakeups should all be managed separately. The `Context` type solves this by providing access to a value of type `Waker`, which can be used to wake up a specific task.

Task Wakeups with `Waker`

It's common that futures aren't able to complete the first time they are `poll`ed. When this happens, the future needs to ensure that it is polled again once it is ready to make more progress. This is done with the `Waker` type.

Each time a future is polled, it is polled as part of a "task". Tasks are the top-level futures that have been submitted to an executor.

`Waker` provides a `wake()` method that can be used to tell the executor that the associated task should be awoken. When `wake()` is called, the executor knows that the task associated with the `Waker` is ready to make progress, and its future should be polled again.

`Waker` also implements `clone()` so that it can be copied around and stored.

Let's try implementing a simple timer future using `Waker`.

Applied: Build a Timer

For the sake of the example, we'll just spin up a new thread when the timer is created, sleep for the required time, and then signal the timer future when the time window has elapsed.

Here are the imports we'll need to get started:

```
use {
    std::{
        future::Future,
        pin::Pin,
        sync::{Arc, Mutex},
        task::{Context, Poll, Waker},
        thread,
        time::Duration,
    },
};
```

Let's start by defining the future type itself. Our future needs a way for the thread to communicate that the timer has elapsed and the future should complete. We'll use a shared `Arc<Mutex<..>>` value to communicate between the thread and the future.

```
pub struct TimerFuture {
    shared_state: Arc<Mutex<SharedState>>,
}

/// Shared state between the future and the waiting thread
struct SharedState {
    /// Whether or not the sleep time has elapsed
    completed: bool,

    /// The waker for the task that `TimerFuture` is running on.
    /// The thread can use this after setting `completed = true` to tell
    /// `TimerFuture`'s task to wake up, see that `completed = true`, and
    /// move forward.
    waker: Option<Waker>,
}
```

Now, let's actually write the `Future` implementation!

```
impl Future for TimerFuture {
    type Output = ();
    fn poll(self: Pin<&mut Self>, cx: &mut Context<'_>) -> Poll<Self::Output> {
        // Look at the shared state to see if the timer has already completed.
        let mut shared_state = self.shared_state.lock().unwrap();
        if shared_state.completed {
            Poll::Ready(())
        } else {
            // Set waker so that the thread can wake up the current task
            // when the timer has completed, ensuring that the future is polled
            // again and sees that `completed = true`.
            //
            // It's tempting to do this once rather than repeatedly cloning
            // the waker each time. However, the `TimerFuture` can move between
            // tasks on the executor, which could cause a stale waker pointing
            // to the wrong task, preventing `TimerFuture` from waking up
            // correctly.
            //
            // N.B. it's possible to check for this using the `Waker::will_wake`
            // function, but we omit that here to keep things simple.
            shared_state.waker = Some(cx.waker().clone());
            Poll::Pending
        }
    }
}
```

Pretty simple, right? If the thread has set `shared_state.completed = true`, we're done! Otherwise, we clone the `Waker` for the current task and pass it to `shared_state.waker` so that the thread can wake the task back up.

Importantly, we have to update the `Waker` every time the future is polled because the future may have moved to a different task with a different `Waker`. This will happen when futures

are passed around between tasks after being polled.

Finally, we need the API to actually construct the timer and start the thread:

```
impl TimerFuture {
    /// Create a new `TimerFuture` which will complete after the provided
    /// timeout.
    pub fn new(duration: Duration) -> Self {
        let shared_state = Arc::new(Mutex::new(SharedState {
            completed: false,
            waker: None,
        }));

        // Spawn the new thread
        let thread_shared_state = shared_state.clone();
        thread::spawn(move || {
            thread::sleep(duration);
            let mut shared_state = thread_shared_state.lock().unwrap();
            // Signal that the timer has completed and wake up the last
            // task on which the future was polled, if one exists.
            shared_state.completed = true;
            if let Some(waker) = shared_state.waker.take() {
                waker.wake()
            }
        });

        TimerFuture { shared_state }
    }
}
```

Woot! That's all we need to build a simple timer future. Now, if only we had an executor to run the future on...

Applied: Build an Executor

Rust's `Future`s are lazy: they won't do anything unless actively driven to completion. One way to drive a future to completion is to `.await` it inside an `async` function, but that just pushes the problem one level up: who will run the futures returned from the top-level `async` functions? The answer is that we need a `Future` executor.

`Future` executors take a set of top-level `Future`s and run them to completion by calling `poll` whenever the `Future` can make progress. Typically, an executor will `poll` a future once to start off. When `Future`s indicate that they are ready to make progress by calling `wake()`, they are placed back onto a queue and `poll` is called again, repeating until the `Future` has completed.

In this section, we'll write our own simple executor capable of running a large number of top-level futures to completion concurrently.

For this example, we depend on the `futures` crate for the `ArcWake` trait, which provides an easy way to construct a `Waker`.

```
[package]
name = "xyz"
version = "0.1.0"
authors = ["XYZ Author"]
edition = "2018"

[dependencies]
futures = "0.3"
```

Next, we need the following imports at the top of `src/main.rs`:

```
use {
    futures::{
        future::{FutureExt, BoxFuture},
        task::{ArcWake, waker_ref},
    },
    std::{
        future::Future,
        sync::{Arc, Mutex},
        sync::mpsc::{sync_channel, SyncSender, Receiver},
        task::{Context, Poll},
        time::Duration,
    },
    // The timer we wrote in the previous section:
    timer_future::TimerFuture,
};
```

Our executor will work by sending tasks to run over a channel. The executor will pull events off of the channel and run them. When a task is ready to do more work (is awoken), it can schedule itself to be polled again by putting itself back onto the channel.

In this design, the executor itself just needs the receiving end of the task channel. The user will get a sending end so that they can spawn new futures. Tasks themselves are just futures that can reschedule themselves, so we'll store them as a future paired with a sender that the task can use to requeue itself.

```
/// Task executor that receives tasks off of a channel and runs them.
struct Executor {
    ready_queue: Receiver<Arc<Task>>,
}

/// `Spawner` spawns new futures onto the task channel.
#[derive(Clone)]
struct Spawner {
    task_sender: SyncSender<Arc<Task>>,
}

/// A future that can reschedule itself to be polled by an `Executor`.
struct Task {
    /// In-progress future that should be pushed to completion.
    ///
    /// The `Mutex` is not necessary for correctness, since we only have
    /// one thread executing tasks at once. However, Rust isn't smart
    /// enough to know that `future` is only mutated from one thread,
    /// so we need use the `Mutex` to prove thread-safety. A production
    /// executor would not need this, and could use `UnsafeCell` instead.
    future: Mutex<Option<BoxFuture<'static, ()>>>,

    /// Handle to place the task itself back onto the task queue.
    task_sender: SyncSender<Arc<Task>>,
}

fn new_executor_and_spawner() -> (Executor, Spawner) {
    // Maximum number of tasks to allow queueing in the channel at once.
    // This is just to make `sync_channel` happy, and wouldn't be present in
    // a real executor.
    const MAX_QUEUED_TASKS: usize = 10_000;
    let (task_sender, ready_queue) = sync_channel(MAX_QUEUED_TASKS);
    (Executor { ready_queue }, Spawner { task_sender })
}
```

Let's also add a method to spawner to make it easy to spawn new futures. This method will take a future type, box it, and create a new `Arc<Task>` with it inside which can be enqueued onto the executor.

```
impl Spawner {
    fn spawn(&self, future: impl Future<Output = ()> + 'static + Send) {
        let future = future.boxed();
        let task = Arc::new(Task {
            future: Mutex::new(Some(future)),
            task_sender: self.task_sender.clone(),
        });
        self.task_sender.send(task).expect("too many tasks queued");
    }
}
```

To poll futures, we'll need to create a `Waker`. As discussed in the task wakeups section, `Waker`s are responsible for scheduling a task to be polled again once `wake` is called. Remember that `Waker`s tell the executor exactly which task has become ready, allowing them to poll just the futures that are ready to make progress. The easiest way to create a

new `Waker` is by implementing the `ArcWake` trait and then using the `waker_ref` or `.into_waker()` functions to turn an `Arc<impl ArcWake>` into a `Waker`. Let's implement `ArcWake` for our tasks to allow them to be turned into `Waker`s and awoken:

```
impl ArcWake for Task {
    fn wake_by_ref(arc_self: &Arc<Self>) {
        // Implement `wake` by sending this task back onto the task channel
        // so that it will be polled again by the executor.
        let cloned = arc_self.clone();
        arc_self.task_sender.send(cloned).expect("too many tasks queued");
    }
}
```

When a `Waker` is created from an `Arc<Task>`, calling `wake()` on it will cause a copy of the `Arc` to be sent onto the task channel. Our executor then needs to pick up the task and poll it. Let's implement that:

```
impl Executor {
    fn run(&self) {
        while let Ok(task) = self.ready_queue.recv() {
            // Take the future, and if it has not yet completed (is still Some),
            // poll it in an attempt to complete it.
            let mut future_slot = task.future.lock().unwrap();
            if let Some(mut future) = future_slot.take() {
                // Create a `LocalWaker` from the task itself
                let waker = waker_ref(&task);
                let context = &mut Context::from_waker(&*waker);
                // `BoxFuture<T>` is a type alias for
                // `Pin<Box<dyn Future<Output = T> + Send + 'static>>`.
                // We can get a `Pin<&mut dyn Future + Send + 'static>`
                // from it by calling the `Pin::as_mut` method.
                if let Poll::Pending = future.as_mut().poll(context) {
                    // We're not done processing the future, so put it
                    // back in its task to be run again in the future.
                    *future_slot = Some(future);
                }
            }
        }
    }
}
```

Congratulations! We now have a working futures executor. We can even use it to run `async/.await` code and custom futures, such as the `TimerFuture` we wrote earlier:

```
fn main() {
    let (executor, spawner) = new_executor_and_spawner();

    // Spawn a task to print before and after waiting on a timer.
    spawner.spawn(async {
        println!("howdy!");
        // Wait for our timer future to complete after two seconds.
        TimerFuture::new(Duration::new(2, 0)).await;
        println!("done!");
    });

    // Drop the spawner so that our executor knows it is finished and won't
    // receive more incoming tasks to run.
    drop(spawner);

    // Run the executor until the task queue is empty.
    // This will print "howdy!", pause, and then print "done!".
    executor.run();
}
```

Executors and System IO

In the previous section on The `Future` Trait, we discussed this example of a future that performed an asynchronous read on a socket:

```
pub struct SocketRead<'a> {
    socket: &'a Socket,
}

impl SimpleFuture for SocketRead<'_> {
    type Output = Vec<u8>;

    fn poll(&mut self, wake: fn()) -> Poll<Self::Output> {
        if self.socket.has_data_to_read() {
            // The socket has data-- read it into a buffer and return it.
            Poll::Ready(self.socket.read_buf())
        } else {
            // The socket does not yet have data.
            //
            // Arrange for `wake` to be called once data is available.
            // When data becomes available, `wake` will be called, and the
            // user of this `Future` will know to call `poll` again and
            // receive data.
            self.socket.set_readable_callback(wake);
            Poll::Pending
        }
    }
}
```

This future will read available data on a socket, and if no data is available, it will yield to the executor, requesting that its task be awoken when the socket becomes readable again. However, it's not clear from this example how the `Socket` type is implemented, and in particular it isn't obvious how the `set_readable_callback` function works. How can we

arrange for `wake()` to be called once the socket becomes readable? One option would be to have a thread that continually checks whether `socket` is readable, calling `wake()` when appropriate. However, this would be quite inefficient, requiring a separate thread for each blocked IO future. This would greatly reduce the efficiency of our async code.

In practice, this problem is solved through integration with an IO-aware system blocking primitive, such as `epoll` on Linux, `kqueue` on FreeBSD and Mac OS, IOCP on Windows, and `port`s on Fuchsia (all of which are exposed through the cross-platform Rust crate `mio`). These primitives all allow a thread to block on multiple asynchronous IO events, returning once one of the events completes. In practice, these APIs usually look something like this:

```
struct IoBlocker {
    /* ... */
}

struct Event {
    // An ID uniquely identifying the event that occurred and was listened for.
    id: usize,

    // A set of signals to wait for, or which occurred.
    signals: Signals,
}

impl IoBlocker {
    /// Create a new collection of asynchronous IO events to block on.
    fn new() -> Self { /* ... */ }

    /// Express an interest in a particular IO event.
    fn add_io_event_interest(
        &self,

        /// The object on which the event will occur
        io_object: &IoObject,

        /// A set of signals that may appear on the `io_object` for
        /// which an event should be triggered, paired with
        /// an ID to give to events that result from this interest.
        event: Event,
    ) { /* ... */ }

    /// Block until one of the events occurs.
    fn block(&self) -> Event { /* ... */ }
}

let mut io_blocker = IoBlocker::new();
io_blocker.add_io_event_interest(
    &socket_1,
    Event { id: 1, signals: READABLE },
);
io_blocker.add_io_event_interest(
    &socket_2,
    Event { id: 2, signals: READABLE | WRITABLE },
);
let event = io_blocker.block();

// prints e.g. "Socket 1 is now READABLE" if socket one became readable.
println!("Socket {:?} is now {:?}", event.id, event.signals);
```

Futures executors can use these primitives to provide asynchronous IO objects such as sockets that can configure callbacks to be run when a particular IO event occurs. In the case of our `SocketRead` example above, the `Socket::set_readable_callback` function might look like the following pseudocode:

```
impl Socket {
    fn set_readable_callback(&self, waker: Waker) {
        // `local_executor` is a reference to the local executor.
        // this could be provided at creation of the socket, but in practice
        // many executor implementations pass it down through thread local
        // storage for convenience.
        let local_executor = self.local_executor;

        // Unique ID for this IO object.
        let id = self.id;

        // Store the local waker in the executor's map so that it can be called
        // once the IO event arrives.
        local_executor.event_map.insert(id, waker);
        local_executor.add_io_event_interest(
            &self.socket_file_descriptor,
            Event { id, signals: READABLE },
        );
    }
}
```

We can now have just one executor thread which can receive and dispatch any IO event to the appropriate `Waker`, which will wake up the corresponding task, allowing the executor to drive more tasks to completion before returning to check for more IO events (and the cycle continues...).

`async`/`.await`

In the first chapter, we took a brief look at `async`/`.await` and used it to build a simple server. This chapter will discuss `async`/`.await` in greater detail, explaining how it works and how `async` code differs from traditional Rust programs.

`async`/`.await` are special pieces of Rust syntax that make it possible to yield control of the current thread rather than blocking, allowing other code to make progress while waiting on an operation to complete.

There are two main ways to use `async`: `async fn` and `async` blocks. Each returns a value that implements the `Future` trait:

```
// `foo()` returns a type that implements `Future<Output = u8>`.
// `foo().await` will result in a value of type `u8`.
async fn foo() -> u8 { 5 }

fn bar() -> impl Future<Output = u8> {
    // This `async` block results in a type that implements
    // `Future<Output = u8>`.
    async {
        let x: u8 = foo().await;
        x + 5
    }
}
```

As we saw in the first chapter, `async` bodies and other futures are lazy: they do nothing until they are run. The most common way to run a `Future` is to `.await` it. When `.await` is called on a `Future`, it will attempt to run it to completion. If the `Future` is blocked, it will yield control of the current thread. When more progress can be made, the `Future` will be picked up by the executor and will resume running, allowing the `.await` to resolve.

`async` Lifetimes

Unlike traditional functions, `async fn`s which take references or other non-`'static` arguments return a `Future` which is bounded by the lifetime of the arguments:

```
// This function:
async fn foo(x: &u8) -> u8 { *x }

// Is equivalent to this function:
fn foo_expanded<'a>(x: &'a u8) -> impl Future<Output = u8> + 'a {
    async move { *x }
}
```

This means that the future returned from an `async fn` must be `.await`ed while its non-`'static` arguments are still valid. In the common case of `.await`ing the future immediately after calling the function (as in `foo(&x).await`) this is not an issue. However, if storing the future or sending it over to another task or thread, this may be an issue.

One common workaround for turning an `async fn` with references-as-arguments into a `'static` future is to bundle the arguments with the call to the `async fn` inside an `async` block:

```
fn bad() -> impl Future<Output = u8> {
    let x = 5;
    borrow_x(&x) // ERROR: `x` does not live long enough
}

fn good() -> impl Future<Output = u8> {
    async {
        let x = 5;
        borrow_x(&x).await
    }
}
```

By moving the argument into the `async` block, we extend its lifetime to match that of the `Future` returned from the call to `good`.

async move

`async` blocks and closures allow the `move` keyword, much like normal closures. An `async move` block will take ownership of the variables it references, allowing it to outlive the current scope, but giving up the ability to share those variables with other code:

```
/// `async` block:
///
/// Multiple different `async` blocks can access the same local variable
/// so long as they're executed within the variable's scope
async fn blocks() {
    let my_string = "foo".to_string();

    let future_one = async {
        // ...
        println!("{}", my_string);
    };

    let future_two = async {
        // ...
        println!("{}", my_string);
    };

    // Run both futures to completion, printing "foo" twice:
    let ((), ()) = futures::join!(future_one, future_two);
}

/// `async move` block:
///
/// Only one `async move` block can access the same captured variable, since
/// captures are moved into the `Future` generated by the `async move` block.
/// However, this allows the `Future` to outlive the original scope of the
/// variable:
fn move_block() -> impl Future<Output = ()> {
    let my_string = "foo".to_string();
    async move {
        // ...
        println!("{}", my_string);
    }
}
```

`.await`ing on a Multithreaded Executor

Note that, when using a multithreaded `Future` executor, a `Future` may move between threads, so any variables used in `async` bodies must be able to travel between threads, as any `.await` can potentially result in a switch to a new thread.

This means that it is not safe to use `Rc`, `&RefCell` or any other types that don't implement the `Send` trait, including references to types that don't implement the `Sync` trait.

(Caveat: it is possible to use these types so long as they aren't in scope during a call to `.await`.)

Similarly, it isn't a good idea to hold a traditional non-futures-aware lock across an `.await`, as it can cause the threadpool to lock up: one task could take out a lock, `.await` and yield to

the executor, allowing another task to attempt to take the lock and cause a deadlock. To avoid this, use the `Mutex` in `futures::lock` rather than the one from `std::sync`.

Pinning

To poll futures, they must be pinned using a special type called `Pin<T>`. If you read the explanation of the `Future` trait in the previous section "Executing `Future`s and Tasks", you'll recognize `Pin` from the `self: Pin<&mut Self>` in the `Future::poll` method's definition. But what does it mean, and why do we need it?

Why Pinning

`Pin` works in tandem with the `Unpin` marker. Pinning makes it possible to guarantee that an object implementing `!Unpin` won't ever be moved. To understand why this is necessary, we need to remember how `async` / `.await` works. Consider the following code:

```
let fut_one = /* ... */;
let fut_two = /* ... */;
async move {
    fut_one.await;
    fut_two.await;
}
```

Under the hood, this creates an anonymous type that implements `Future`, providing a `poll` method that looks something like this:

```
// The `Future` type generated by our `async { ... }` block
struct AsyncFuture {
    fut_one: FutOne,
    fut_two: FutTwo,
    state: State,
}

// List of states our `async` block can be in
enum State {
    AwaitingFutOne,
    AwaitingFutTwo,
    Done,
}

impl Future for AsyncFuture {
    type Output = ();

    fn poll(mut self: Pin<&mut Self>, cx: &mut Context<'_>) -> Poll<()> {
        loop {
            match self.state {
                State::AwaitingFutOne => match self.fut_one.poll(..) {
                    Poll::Ready(()) => self.state = State::AwaitingFutTwo,
                    Poll::Pending => return Poll::Pending,
                }
                State::AwaitingFutTwo => match self.fut_two.poll(..) {
                    Poll::Ready(()) => self.state = State::Done,
                    Poll::Pending => return Poll::Pending,
                }
                State::Done => return Poll::Ready(()),
            }
        }
    }
}
```

When `poll` is first called, it will poll `fut_one`. If `fut_one` can't complete, `AsyncFuture::poll` will return. Future calls to `poll` will pick up where the previous one left off. This process continues until the future is able to successfully complete.

However, what happens if we have an `async` block that uses references? For example:

```
async {
    let mut x = [0; 128];
    let read_into_buf_fut = read_into_buf(&mut x);
    read_into_buf_fut.await;
    println!("{:?}", x);
}
```

What struct does this compile down to?

```
struct ReadIntoBuf<'a> {
    buf: &'a mut [u8], // points to `x` below
}

struct AsyncFuture {
    x: [u8; 128],
    read_into_buf_fut: ReadIntoBuf<'what_lifetime?>,
}
```

Here, the `ReadIntoBuf` future holds a reference into the other field of our structure, `x`. However, if `AsyncFuture` is moved, the location of `x` will move as well, invalidating the pointer stored in `read_into_buf_fut.buf`.

Pinning futures to a particular spot in memory prevents this problem, making it safe to create references to values inside an `async` block.

Pinning in Detail

Let's try to understand pinning by using an slightly simpler example. The problem we encounter above is a problem that ultimately boils down to how we handle references in self-referential types in Rust.

For now our example will look like this:

```
use std::pin::Pin;

#[derive(Debug)]
struct Test {
    a: String,
    b: *const String,
}

impl Test {
    fn new(txt: &str) -> Self {
        Test {
            a: String::from(txt),
            b: std::ptr::null(),
        }
    }

    fn init(&mut self) {
        let self_ref: *const String = &self.a;
        self.b = self_ref;
    }

    fn a(&self) -> &str {
        &self.a
    }

    fn b(&self) -> &String {
        unsafe {&*(self.b)}
    }
}
```

`Test` provides methods to get a reference to the value of the fields `a` and `b`. Since `b` is a reference to `a` we store it as a pointer since the borrowing rules of Rust doesn't allow us to define this lifetime. We now have what we call a self-referential struct.

Our example works fine if we don't move any of our data around as you can observe by running this example:

```
fn main() {
    let mut test1 = Test::new("test1");
    test1.init();
    let mut test2 = Test::new("test2");
    test2.init();

    println!("a: {}, b: {}", test1.a(), test1.b());
    println!("a: {}, b: {}", test2.a(), test2.b());

}
```

We get what we'd expect:

```
a: test1, b: test1
a: test2, b: test2
```

Let's see what happens if we swap `test1` with `test2` and thereby move the data:

```
fn main() {
    let mut test1 = Test::new("test1");
    test1.init();
    let mut test2 = Test::new("test2");
    test2.init();

    println!("a: {}, b: {}", test1.a(), test1.b());
    std::mem::swap(&mut test1, &mut test2);
    println!("a: {}, b: {}", test2.a(), test2.b());

}
```

Naively, we could think that what we should get a debug print of `test1` two times like this:

```
a: test1, b: test1
a: test1, b: test1
```

But instead we get:

```
a: test1, b: test1
a: test1, b: test2
```

The pointer to `test2.b` still points to the old location which is inside `test1` now. The struct is not self-referential anymore, it holds a pointer to a field in a different object. That means we can't rely on the lifetime of `test2.b` to be tied to the lifetime of `test2` anymore.

If you're still not convinced, this should at least convince you:

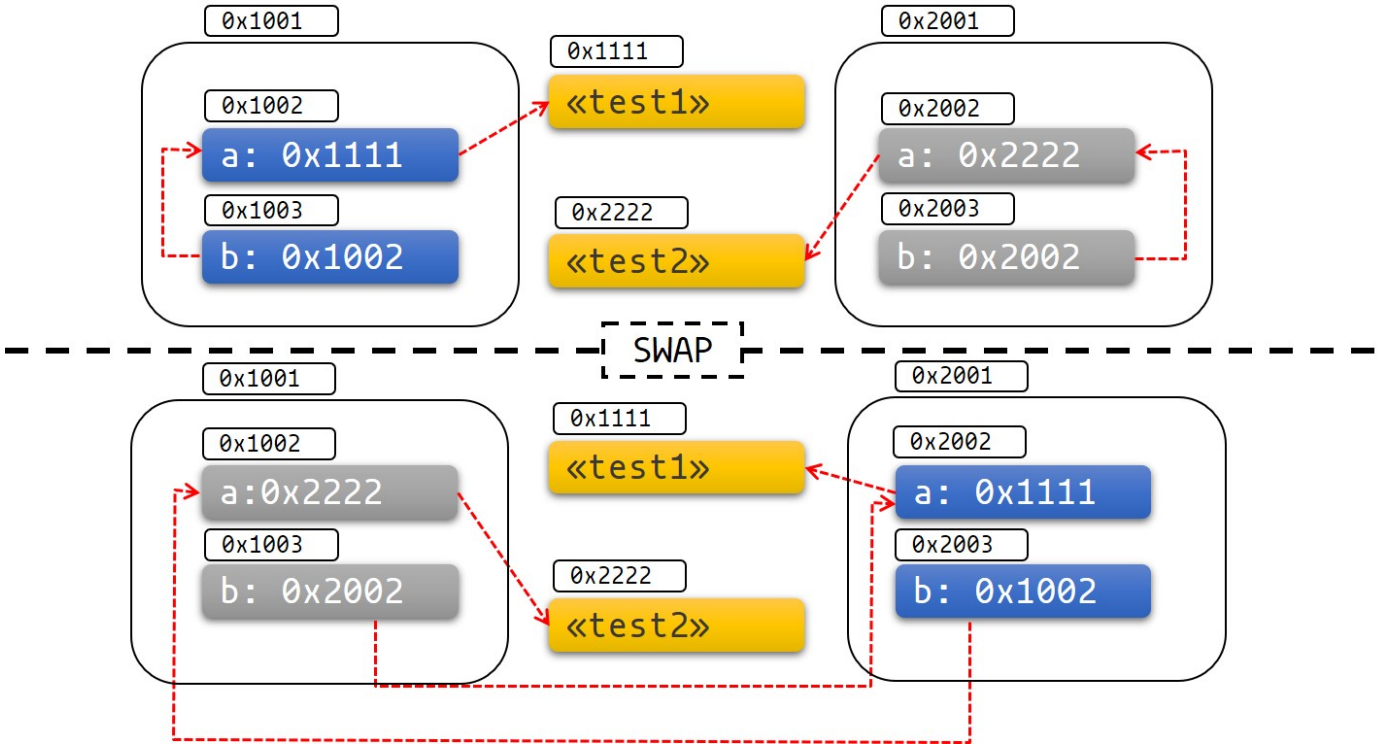
```
fn main() {
    let mut test1 = Test::new("test1");
    test1.init();
    let mut test2 = Test::new("test2");
    test2.init();

    println!("a: {}, b: {}", test1.a(), test1.b());
    std::mem::swap(&mut test1, &mut test2);
    test1.a = "I've totally changed now!".to_string();
    println!("a: {}, b: {}", test2.a(), test2.b());

}
```

The diagram below can help visualize what's going on:

Fig 1: Before and after swap



It's easy to get this to show UB and fail in other spectacular ways as well.

Pinning in Practice

Let's see how pinning and the `Pin` type can help us solve this problem.

The `Pin` type wraps pointer types, guaranteeing that the values behind the pointer won't be moved. For example, `Pin<&mut T>`, `Pin<&T>`, `Pin<Box<T>>` all guarantee that `T` won't be moved if `T: !Unpin`.

Most types don't have a problem being moved. These types implement a trait called `Unpin`. Pointers to `Unpin` types can be freely placed into or taken out of `Pin`. For example, `u8` is `Unpin`, so `Pin<&mut u8>` behaves just like a normal `&mut u8`.

However, types that can't be moved after they're pinned has a marker called `!Unpin`. Futures created by async/await is an example of this.

Pinning to the Stack

Back to our example. We can solve our problem by using `Pin`. Let's take a look at what our example would look like we required a pinned pointer instead:

```
use std::pin::Pin;
use std::marker::PhantomPinned;

#[derive(Debug)]
struct Test {
    a: String,
    b: *const String,
    _marker: PhantomPinned,
}

impl Test {
    fn new(txt: &str) -> Self {
        Test {
            a: String::from(txt),
            b: std::ptr::null(),
            _marker: PhantomPinned, // This makes our type `!Unpin`
        }
    }
    fn init<'a>(self: Pin<&'a mut Self>) {
        let self_ptr: *const String = &self.a;
        let this = unsafe { self.get_unchecked_mut() };
        this.b = self_ptr;
    }

    fn a<'a>(self: Pin<&'a Self>) -> &'a str {
        &self.get_ref().a
    }

    fn b<'a>(self: Pin<&'a Self>) -> &'a String {
        unsafe { &*(self.b) }
    }
}
```

Pinning an object to the stack will always be `unsafe` if our type implements `!Unpin`. You can use a crate like `pin_utils` to avoid writing our own `unsafe` code when pinning to the stack.

Below, we pin the objects `test1` and `test2` to the stack:

```
pub fn main() {
    // test1 is safe to move before we initialize it
    let mut test1 = Test::new("test1");
    // Notice how we shadow `test1` to prevent it from being accessed again
    let mut test1 = unsafe { Pin::new_unchecked(&mut test1) };
    Test::init(test1.as_mut());

    let mut test2 = Test::new("test2");
    let mut test2 = unsafe { Pin::new_unchecked(&mut test2) };
    Test::init(test2.as_mut());

    println!("a: {}, b: {}", Test::a(test1.as_ref()), Test::b(test1.as_ref()));
    println!("a: {}, b: {}", Test::a(test2.as_ref()), Test::b(test2.as_ref()));
}
```

Now, if we try to move our data now we get a compilation error:

```
pub fn main() {
    let mut test1 = Test::new("test1");
    let mut test1 = unsafe { Pin::new_unchecked(&mut test1) };
    Test::init(test1.as_mut());

    let mut test2 = Test::new("test2");
    let mut test2 = unsafe { Pin::new_unchecked(&mut test2) };
    Test::init(test2.as_mut());

    println!("a: {}, b: {}", Test::a(test1.as_ref()), Test::b(test1.as_ref()));
    std::mem::swap(test1.get_mut(), test2.get_mut());
    println!("a: {}, b: {}", Test::a(test2.as_ref()), Test::b(test2.as_ref()));
}
```

The type system prevents us from moving the data.

> It's important to note that stack pinning will always rely on guarantees you give when writing `unsafe`. While we know that the *pointee* of `&'a mut T` is pinned for the lifetime of `'a` we can't know if the data `&'a mut T` points to isn't moved after `'a` ends. If it does it will violate the Pin contract.
>
> A mistake that is easy to make is forgetting to shadow the original variable since you could drop the `Pin` and move the data after `&'a mut T` like shown below (which violates the Pin contract):
>
> ```
> fn main() {
>    let mut test1 = Test::new("test1");
>    let mut test1_pin = unsafe { Pin::new_unchecked(&mut test1) };
>    Test::init(test1_pin.as_mut());
>    drop(test1_pin);
>    println!(r#"test1.b points to "test1": {:?}..."#, test1.b);
>    let mut test2 = Test::new("test2");
>    mem::swap(&mut test1, &mut test2);
>    println!("... and now it points nowhere: {:?}", test1.b);
> }
> ```

Pinning to the Heap

Pinning an `!Unpin` type to the heap gives our data a stable address so we know that the data we point to can't move after it's pinned. In contrast to stack pinning, we know that the data will be pinned for the lifetime of the object.

```
use std::pin::Pin;
use std::marker::PhantomPinned;

#[derive(Debug)]
struct Test {
    a: String,
    b: *const String,
    _marker: PhantomPinned,
}

impl Test {
    fn new(txt: &str) -> Pin<Box<Self>> {
        let t = Test {
            a: String::from(txt),
            b: std::ptr::null(),
            _marker: PhantomPinned,
        };
        let mut boxed = Box::pin(t);
        let self_ptr: *const String = &boxed.as_ref().a;
        unsafe { boxed.as_mut().get_unchecked_mut().b = self_ptr };

        boxed
    }

    fn a<'a>(self: Pin<&'a Self>) -> &'a str {
        &self.get_ref().a
    }

    fn b<'a>(self: Pin<&'a Self>) -> &'a String {
        unsafe { &*(self.b) }
    }
}

pub fn main() {
    let mut test1 = Test::new("test1");
    let mut test2 = Test::new("test2");

    println!("a: {}, b: {}",test1.as_ref().a(), test1.as_ref().b());
    println!("a: {}, b: {}",test2.as_ref().a(), test2.as_ref().b());
}
```

Some functions require the futures they work with to be `Unpin`. To use a `Future` or `Stream` that isn't `Unpin` with a function that requires `Unpin` types, you'll first have to pin the value using either `Box::pin` (to create a `Pin<Box<T>>`) or the `pin_utils::pin_mut!` macro (to create a `Pin<&mut T>`). `Pin<Box<Fut>>` and `Pin<&mut Fut>` can both be used as futures, and both implement `Unpin`.

For example:

```
use pin_utils::pin_mut; // `pin_utils` is a handy crate available on crates.io

// A function which takes a `Future` that implements `Unpin`.
fn execute_unpin_future(x: impl Future<Output = ()> + Unpin) { /* ... */ }

let fut = async { /* ... */ };
execute_unpin_future(fut); // Error: `fut` does not implement `Unpin` trait

// Pinning with `Box`:
let fut = async { /* ... */ };
let fut = Box::pin(fut);
execute_unpin_future(fut); // OK

// Pinning with `pin_mut!`:
let fut = async { /* ... */ };
pin_mut!(fut);
execute_unpin_future(fut); // OK
```

Summary

1. If `T: Unpin` (which is the default), then `Pin<'a, T>` is entirely equivalent to `&'a mut T`. in other words: `Unpin` means it's OK for this type to be moved even when pinned, so `Pin` will have no effect on such a type.
2. Getting a `&mut T` to a pinned T requires unsafe if `T: !Unpin`.
3. Most standard library types implement `Unpin`. The same goes for most "normal" types you encounter in Rust. A `Future` generated by async/await is an exception to this rule.
4. You can add a `!Unpin` bound on a type on nightly with a feature flag, or by adding `std::marker::PhantomPinned` to your type on stable.
5. You can either pin data to the stack or to the heap.
6. Pinning a `!Unpin` object to the stack requires `unsafe`
7. Pinning a `!Unpin` object to the heap does not require `unsafe`. There is a shortcut for doing this using `Box::pin`.
8. For pinned data where `T: !Unpin` you have to maintain the invariant that its memory will not get invalidated or repurposed *from the moment it gets pinned until when drop* is called. This is an important part of the *pin contract*.

The `Stream` Trait

The `Stream` trait is similar to `Future` but can yield multiple values before completing, similar to the `Iterator` trait from the standard library:

```
trait Stream {
    /// The type of the value yielded by the stream.
    type Item;

    /// Attempt to resolve the next item in the stream.
    /// Returns `Poll::Pending` if not ready, `Poll::Ready(Some(x))` if a value
    /// is ready, and `Poll::Ready(None)` if the stream has completed.
    fn poll_next(self: Pin<&mut Self>, cx: &mut Context<'_>)
        -> Poll<Option<Self::Item>>;
}
```

One common example of a `Stream` is the `Receiver` for the channel type from the `futures` crate. It will yield `Some(val)` every time a value is sent from the `Sender` end, and will yield `None` once the `Sender` has been dropped and all pending messages have been received:

```
async fn send_recv() {
    const BUFFER_SIZE: usize = 10;
    let (mut tx, mut rx) = mpsc::channel::<i32>(BUFFER_SIZE);

    tx.send(1).await.unwrap();
    tx.send(2).await.unwrap();
    drop(tx);

    // `StreamExt::next` is similar to `Iterator::next`, but returns a
    // type that implements `Future<Output = Option<T>>`.
    assert_eq!(Some(1), rx.next().await);
    assert_eq!(Some(2), rx.next().await);
    assert_eq!(None, rx.next().await);
}
```

Iteration and Concurrency

Similar to synchronous `Iterator`s, there are many different ways to iterate over and process the values in a `Stream`. There are combinator-style methods such as `map`, `filter`, and `fold`, and their early-exit-on-error cousins `try_map`, `try_filter`, and `try_fold`.

Unfortunately, `for` loops are not usable with `Stream`s, but for imperative-style code, `while let` and the `next`/`try_next` functions can be used:

```
async fn sum_with_next(mut stream: Pin<&mut dyn Stream<Item = i32>>) -> i32 {
    use futures::stream::StreamExt; // for `next`
    let mut sum = 0;
    while let Some(item) = stream.next().await {
        sum += item;
    }
    sum
}

async fn sum_with_try_next(
    mut stream: Pin<&mut dyn Stream<Item = Result<i32, io::Error>>>,
) -> Result<i32, io::Error> {
    use futures::stream::TryStreamExt; // for `try_next`
    let mut sum = 0;
    while let Some(item) = stream.try_next().await? {
        sum += item;
    }
    Ok(sum)
}
```

However, if we're just processing one element at a time, we're potentially leaving behind opportunity for concurrency, which is, after all, why we're writing async code in the first place. To process multiple items from a stream concurrently, use the `for_each_concurrent` and `try_for_each_concurrent` methods:

```
async fn jump_around(
    mut stream: Pin<&mut dyn Stream<Item = Result<u8, io::Error>>>,
) -> Result<(), io::Error> {
    use futures::stream::TryStreamExt; // for `try_for_each_concurrent`
    const MAX_CONCURRENT_JUMPERS: usize = 100;

    stream.try_for_each_concurrent(MAX_CONCURRENT_JUMPERS, |num| async move {
        jump_n_times(num).await?;
        report_n_jumps(num).await?;
        Ok(())
    }).await?;

    Ok(())
}
```

Executing Multiple Futures at a Time

Up until now, we've mostly executed futures by using `.await`, which blocks the current task until a particular `Future` completes. However, real asynchronous applications often need to execute several different operations concurrently.

In this chapter, we'll cover some ways to execute multiple asynchronous operations at the same time:

- `join!`: waits for futures to all complete
- `select!`: waits for one of several futures to complete

- Spawning: creates a top-level task which ambiently runs a future to completion
- `FuturesUnordered`: a group of futures which yields the result of each subfuture

join!

The `futures::join` macro makes it possible to wait for multiple different futures to complete while executing them all concurrently.

join!

When performing multiple asynchronous operations, it's tempting to simply `.await` them in a series:

```
async fn get_book_and_music() -> (Book, Music) {
    let book = get_book().await;
    let music = get_music().await;
    (book, music)
}
```

However, this will be slower than necessary, since it won't start trying to `get_music` until after `get_book` has completed. In some other languages, futures are ambiently run to completion, so two operations can be run concurrently by first calling each `async fn` to start the futures, and then awaiting them both:

```
// WRONG -- don't do this
async fn get_book_and_music() -> (Book, Music) {
    let book_future = get_book();
    let music_future = get_music();
    (book_future.await, music_future.await)
}
```

However, Rust futures won't do any work until they're actively `.await`ed. This means that the two code snippets above will both run `book_future` and `music_future` in series rather than running them concurrently. To correctly run the two futures concurrently, use `futures::join!`:

```
use futures::join;

async fn get_book_and_music() -> (Book, Music) {
    let book_fut = get_book();
    let music_fut = get_music();
    join!(book_fut, music_fut)
}
```

The value returned by `join!` is a tuple containing the output of each `Future` passed in.

`try_join!`

For futures which return `Result`, consider using `try_join!` rather than `join!`. Since `join!` only completes once all subfutures have completed, it'll continue processing other futures even after one of its subfutures has returned an `Err`.

Unlike `join!`, `try_join!` will complete immediately if one of the subfutures returns an error.

```
use futures::try_join;

async fn get_book() -> Result<Book, String> { /* ... */ Ok(Book) }
async fn get_music() -> Result<Music, String> { /* ... */ Ok(Music) }

async fn get_book_and_music() -> Result<(Book, Music), String> {
    let book_fut = get_book();
    let music_fut = get_music();
    try_join!(book_fut, music_fut)
}
```

Note that the futures passed to `try_join!` must all have the same error type. Consider using the `.map_err(|e| ...)` and `.err_into()` functions from `futures::future::TryFutureExt` to consolidate the error types:

```
use futures::{
    future::TryFutureExt,
    try_join,
};

async fn get_book() -> Result<Book, ()> { /* ... */ Ok(Book) }
async fn get_music() -> Result<Music, String> { /* ... */ Ok(Music) }

async fn get_book_and_music() -> Result<(Book, Music), String> {
    let book_fut = get_book().map_err(|()| "Unable to get book".to_string());
    let music_fut = get_music();
    try_join!(book_fut, music_fut)
}
```

`select!`

The `futures::select` macro runs multiple futures simultaneously, allowing the user to respond as soon as any future completes.

```
use futures::{
    future::FutureExt, // for `.fuse()`
    pin_mut,
    select,
};

async fn task_one() { /* ... */ }
async fn task_two() { /* ... */ }

async fn race_tasks() {
    let t1 = task_one().fuse();
    let t2 = task_two().fuse();

    pin_mut!(t1, t2);

    select! {
        () = t1 => println!("task one completed first"),
        () = t2 => println!("task two completed first"),
    }
}
```

The function above will run both `t1` and `t2` concurrently. When either `t1` or `t2` finishes, the corresponding handler will call `println!`, and the function will end without completing the remaining task.

The basic syntax for `select` is `<pattern> = <expression> => <code>,`, repeated for as many futures as you would like to `select` over.

`default => ...` and `complete => ...`

`select` also supports `default` and `complete` branches.

A `default` branch will run if none of the futures being `select`ed over are yet complete. A `select` with a `default` branch will therefore always return immediately, since `default` will be run if none of the other futures are ready.

`complete` branches can be used to handle the case where all futures being `select`ed over have completed and will no longer make progress. This is often handy when looping over a `select!`.

```
use futures::{future, select};

async fn count() {
    let mut a_fut = future::ready(4);
    let mut b_fut = future::ready(6);
    let mut total = 0;

    loop {
        select! {
            a = a_fut => total += a,
            b = b_fut => total += b,
            complete => break,
            default => unreachable!(), // never runs (futures are ready, then
complete)
        };
    }
    assert_eq!(total, 10);
}
```

Interaction with `Unpin` and `FusedFuture`

One thing you may have noticed in the first example above is that we had to call `.fuse()` on the futures returned by the two `async fn`s, as well as pinning them with `pin_mut`. Both of these calls are necessary because the futures used in `select` must implement both the `Unpin` trait and the `FusedFuture` trait.

`Unpin` is necessary because the futures used by `select` are not taken by value, but by mutable reference. By not taking ownership of the future, uncompleted futures can be used again after the call to `select`.

Similarly, the `FusedFuture` trait is required because `select` must not poll a future after it has completed. `FusedFuture` is implemented by futures which track whether or not they have completed. This makes it possible to use `select` in a loop, only polling the futures which still have yet to complete. This can be seen in the example above, where `a_fut` or `b_fut` will have completed the second time through the loop. Because the future returned by `future::ready` implements `FusedFuture`, it's able to tell `select` not to poll it again.

Note that streams have a corresponding `FusedStream` trait. Streams which implement this trait or have been wrapped using `.fuse()` will yield `FusedFuture` futures from their `.next()` / `.try_next()` combinators.

```
use futures::{
    stream::{Stream, StreamExt, FusedStream},
    select,
};

async fn add_two_streams(
    mut s1: impl Stream<Item = u8> + FusedStream + Unpin,
    mut s2: impl Stream<Item = u8> + FusedStream + Unpin,
) -> u8 {
    let mut total = 0;

    loop {
        let item = select! {
            x = s1.next() => x,
            x = s2.next() => x,
            complete => break,
        };
        if let Some(next_num) = item {
            total += next_num;
        }
    }

    total
}
```

Concurrent tasks in a `select` loop with `Fuse` and `FuturesUnordered`

One somewhat hard-to-discover but handy function is `Fuse::terminated()`, which allows constructing an empty future which is already terminated, and can later be filled in with a future that needs to be run.

This can be handy when there's a task that needs to be run during a `select` loop but which is created inside the `select` loop itself.

Note the use of the `.select_next_some()` function. This can be used with `select` to only run the branch for `Some(_)` values returned from the stream, ignoring `None`s.

```
use futures::{
    future::{Fuse, FusedFuture, FutureExt},
    stream::{FusedStream, Stream, StreamExt},
    pin_mut,
    select,
};

async fn get_new_num() -> u8 { /* ... */ 5 }

async fn run_on_new_num(_: u8) { /* ... */ }

async fn run_loop(
    mut interval_timer: impl Stream<Item = ()> + FusedStream + Unpin,
    starting_num: u8,
) {
    let run_on_new_num_fut = run_on_new_num(starting_num).fuse();
    let get_new_num_fut = Fuse::terminated();
    pin_mut!(run_on_new_num_fut, get_new_num_fut);
    loop {
        select! {
            () = interval_timer.select_next_some() => {
                // The timer has elapsed. Start a new `get_new_num_fut`
                // if one was not already running.
                if get_new_num_fut.is_terminated() {
                    get_new_num_fut.set(get_new_num().fuse());
                }
            },
            new_num = get_new_num_fut => {
                // A new number has arrived-- start a new `run_on_new_num_fut`,
                // dropping the old one.
                run_on_new_num_fut.set(run_on_new_num(new_num).fuse());
            },
            // Run the `run_on_new_num_fut`
            () = run_on_new_num_fut => {},
            // panic if everything completed, since the `interval_timer` should
            // keep yielding values indefinitely.
            complete => panic!("`interval_timer` completed unexpectedly"),
        }
    }
}
```

When many copies of the same future need to be run simultaneously, use the `FuturesUnordered` type. The following example is similar to the one above, but will run each copy of `run_on_new_num_fut` to completion, rather than aborting them when a new one is created. It will also print out a value returned by `run_on_new_num_fut`.

```
use futures::{
    future::{Fuse, FusedFuture, FutureExt},
    stream::{FusedStream, FuturesUnordered, Stream, StreamExt},
    pin_mut,
    select,
};

async fn get_new_num() -> u8 { /* ... */ 5 }

async fn run_on_new_num(_: u8) -> u8 { /* ... */ 5 }

// Runs `run_on_new_num` with the latest number
// retrieved from `get_new_num`.
//
// `get_new_num` is re-run every time a timer elapses,
// immediately cancelling the currently running
// `run_on_new_num` and replacing it with the newly
// returned value.
async fn run_loop(
    mut interval_timer: impl Stream<Item = ()> + FusedStream + Unpin,
    starting_num: u8,
) {
    let mut run_on_new_num_futs = FuturesUnordered::new();
    run_on_new_num_futs.push(run_on_new_num(starting_num));
    let get_new_num_fut = Fuse::terminated();
    pin_mut!(get_new_num_fut);
    loop {
        select! {
            () = interval_timer.select_next_some() => {
                // The timer has elapsed. Start a new `get_new_num_fut`
                // if one was not already running.
                if get_new_num_fut.is_terminated() {
                    get_new_num_fut.set(get_new_num().fuse());
                }
            },
            new_num = get_new_num_fut => {
                // A new number has arrived-- start a new `run_on_new_num_fut`.
                run_on_new_num_futs.push(run_on_new_num(new_num));
            },
            // Run the `run_on_new_num_futs` and check if any have completed
            res = run_on_new_num_futs.select_next_some() => {
                println!("run_on_new_num_fut returned {:?}", res);
            },
            // panic if everything completed, since the `interval_timer` should
            // keep yielding values indefinitely.
            complete => panic!("`interval_timer` completed unexpectedly"),
        }
    }
}
```

Workarounds to Know and Love

Rust's `async` support is still fairly new, and there are a handful of highly-requested features still under active development, as well as some subpar diagnostics. This chapter will discuss some common pain points and explain how to work around them.

Return Type Errors

In a typical Rust function, returning a value of the wrong type will result in an error that looks something like this:

```
error[E0308]: mismatched types
 --> src/main.rs:2:12
  |
1 | fn foo() {
  |           - expected `()` because of default return type
2 |     return "foo"
  |            ^^^^^ expected (), found reference
  |
  = note: expected type `()`
             found type `&'static str`
```

However, the current `async fn` support doesn't know to "trust" the return type written in the function signature, causing mismatched or even reversed-sounding errors. For example, the function `async fn foo() { "foo" }` results in this error:

```
error[E0271]: type mismatch resolving `<impl std::future::Future as
std::future::Future>::Output == ()`
 --> src/lib.rs:1:16
  |
1 | async fn foo() {
  |                ^ expected &str, found ()
  |
  = note: expected type `&str`
             found type `()`
  = note: the return type of a function must have a statically known size
```

The error says that it *expected* `&str` and found `()`, which is actually the exact opposite of what you'd want. This is because the compiler is incorrectly trusting the function body to return the correct type.

The workaround for this issue is to recognize that errors pointing to the function signature with the message "expected `SomeType`, found `OtherType`" usually indicate that one or more return sites are incorrect.

A fix to this issue is being tracked in this bug.

`?` in `async` Blocks

Just as in `async fn`, it's common to use `?` inside `async` blocks. However, the return type of `async` blocks isn't explicitly stated. This can cause the compiler to fail to infer the error type of the `async` block.

For example, this code:

```
let fut = async {
    foo().await?;
    bar().await?;
    Ok(())
};
```

will trigger this error:

```
error[E0282]: type annotations needed
 --> src/main.rs:5:9
  |
4 |     let fut = async {
  |         --- consider giving `fut` a type
5 |         foo().await?;
  |         ^^^^^^^^^^^^ cannot infer type
```

Unfortunately, there's currently no way to "give `fut` a type", nor a way to explicitly specify the return type of an `async` block. To work around this, use the "turbofish" operator to supply the success and error types for the `async` block:

```
let fut = async {
    foo().await?;
    bar().await?;
    Ok::<(), MyError>(()) // <- note the explicit type annotation here
};
```

`Send` Approximation

Some `async fn` state machines are safe to be sent across threads, while others are not. Whether or not an `async fn` `Future` is `Send` is determined by whether a non-`Send` type is held across an `.await` point. The compiler does its best to approximate when values may be held across an `.await` point, but this analysis is too conservative in a number of places today.

For example, consider a simple non-`Send` type, perhaps a type which contains an `Rc`:

```
use std::rc::Rc;

#[derive(Default)]
struct NotSend(Rc<()>);
```

Variables of type `NotSend` can briefly appear as temporaries in `async fn`s even when the resulting `Future` type returned by the `async fn` must be `Send`:

```
async fn bar() {}
async fn foo() {
    NotSend::default();
    bar().await;
}

fn require_send(_: impl Send) {}

fn main() {
    require_send(foo());
}
```

However, if we change `foo` to store `NotSend` in a variable, this example no longer compiles:

```
async fn foo() {
    let x = NotSend::default();
    bar().await;
}
```

```
error[E0277]: `std::rc::Rc<()>` cannot be sent between threads safely
  --> src/main.rs:15:5
   |
15 |     require_send(foo());
   |     ^^^^^^^^^^^^ `std::rc::Rc<()>` cannot be sent between threads safely
   |
   = help: within `impl std::future::Future`, the trait `std::marker::Send` is

   | ^^^^^^^^^^^^^^^^^^^^^^^^^^^^^

error: aborting due to previous error

For more information about this error, try `rustc --explain E0277`.
```

This error is correct. If we store `x` into a variable, it won't be dropped until after the `.await`, at which point the `async fn` may be running on a different thread. Since `Rc` is not `Send`,

allowing it to travel across threads would be unsound. One simple solution to this would be to `drop` the `Rc` before the `.await`, but unfortunately that does not work today.

In order to successfully work around this issue, you may have to introduce a block scope encapsulating any non-`Send` variables. This makes it easier for the compiler to tell that these variables do not live across an `.await` point.

```
async fn foo() {
    {
        let x = NotSend::default();
    }
    bar().await;
}
```

Recursion

Internally, `async fn` creates a state machine type containing each sub-`Future` being `.await`ed. This makes recursive `async fn`s a little tricky, since the resulting state machine type has to contain itself:

```
// This function:
async fn foo() {
    step_one().await;
    step_two().await;
}
// generates a type like this:
enum Foo {
    First(StepOne),
    Second(StepTwo),
}

// So this function:
async fn recursive() {
    recursive().await;
    recursive().await;
}

// generates a type like this:
enum Recursive {
    First(Recursive),
    Second(Recursive),
}
```

This won't work-- we've created an infinitely-sized type! The compiler will complain:

```
error[E0733]: recursion in an `async fn` requires boxing
 --> src/lib.rs:1:22
  |
1 | async fn recursive() {
  |                      ^ an `async fn` cannot invoke itself directly
  |
  = note: a recursive `async fn` must be rewritten to return a boxed future.
```

In order to allow this, we have to introduce an indirection using `Box`. Unfortunately, compiler limitations mean that just wrapping the calls to `recursive()` in `Box::pin` isn't enough. To make this work, we have to make `recursive` into a non-`async` function which returns a `.boxed()` `async` block:

```
use futures::future::{BoxFuture, FutureExt};

fn recursive() -> BoxFuture<'static, ()> {
    async move {
        recursive().await;
        recursive().await;
    }.boxed()
}
```

`async` in Traits

Currently, `async fn` cannot be used in traits. The reasons for this are somewhat complex, but there are plans to remove this restriction in the future.

In the meantime, however, this can be worked around using the async-trait crate from crates.io.

Note that using these trait methods will result in a heap allocation per-function-call. This is not a significant cost for the vast majority of applications, but should be considered when deciding whether to use this functionality in the public API of a low-level function that is expected to be called millions of times a second.
